ABSTRACT

We present new observations of two anomalous X-ray pulsars (AXP) 4U 0142+61 and 1E 1048.1–5937 made in 1998 with the *ASCA*. The energy spectra of these two AXPs are found to consist of two components, a power-law and a blackbody emission from the neutron star surface. These observations, when compared to earlier *ASCA* observations in 1994 show remarkable stability in the intensity, spectral shape and pulse profile. However, we find that the spin-down rate in 1E 1048.1–5937 is not constant. In this source, we have clearly identified three epochs with spin-down rates different from each other and the average value. This has very strong implications for the magnetar hypothesis of AXPs. We also note that the spin-down rate and its variations in 1E 1048.1–5937 are much larger than what can normally be produced by an accretion disk with very low mass accretion rate corresponding to its low X-ray luminosity.

Subject headings: stars: neutron — Pulsars: individual (4U 0142+61, 1E 1048.1–5937)

1. Introduction

Some X-ray pulsars are known to have remarkable similarity in their properties which are different from other binary or isolated X-ray pulsars (Mereghetti & Stella 1995). The properties common to most of these objects are a) pulse period in a small range of 5–12 s, b) monotonous spin down with $P/\dot{P}$ in the range of $5 \times 10^{11} - 1.3 \times 10^{13}$ s, c) identical X-ray spectrum consisting of steep power-law ($\Gamma = 3 - 4$) and black body component ($kT \sim 0.5$ keV), d) stable X-ray luminosity ($10^{34} - 10^{36}$ ergs s^{-1}) for years, e) faint or unidentified optical counterpart, and f) no evidence of orbital motion. The sources also have a galactic distribution, most of these are within $|b| \leq 0.5^\circ$ and all are probably young ($\sim 10^4$ yr) because of their association with SNR or molecular clouds. The objects in which all the properties mentioned above have been observed are 4U 0142+61, 1E 2259+586, 1E 1048.1–5937, 1RXS J170849.0–400910 and 1E 1841–045 (Kes 73). Two more objects, AX J1845.0–0300 (Torii et al. 1998) and RX J0720.4–3125 (Haberl et al. 1996), also probably belong to the same class but to establish their AXP candidacy, more X-ray observations are required to measure their pulse period variations, search for possible pulse arrival time delay and investigate the flux stability. Classification of an object as AXP only from some properties similar to the above is not very firm. 4U 1626–67, probably a binary system, showed both spin-up and spin-down (Chakrabarty et al. 1997) and also has an optically bright accretion disk (Middleditch et al. 1981). Another one object RX J1838.4–0301 (Schwentker 1994), does not have stable intensity and pulsations are also not always detectable (Song et al. 1999). Therefore, these two objects are not AXPs.

Considering the strong similarity between these handful of sources, it has been proposed that they have same physical nature and different scenarios have been proposed to explain the observed properties. The prominent models are a) accretion from low mass binary companion (Mereghetti & Stella 1995), b) single neutron star accreting from molecular cloud, or a product of common envelope evolution (Thorne-Żytkov object) of close high mass X-ray binaries in which a solitary neutron star accretes matter from a fossil disk (van Paradijs, Taam, & van den Heuvel 1995; Ghosh, Angelini, & White 1997), and c) extremely high magnetic field neutron star radi-

ating X-rays due to magnetic field decay (Thompson & Duncan 1996). Unlike the radio pulsars and rotationally powered X-ray pulsars, in the AXPs, the spin-down rate is not large enough to power the observed X-ray emission.

Among the 90 or so known X-ray pulsars (Nagase 1999), direct evidence of binary nature is known for more than 35 sources (van Paradijs 1995). Including the indirect evidences this number can be upto about 65 and 7 pulsars are isolated stars in SNR and are powered by rotational energy losses. In the rest of the pulsars, in which no binary signature is known, it is often due to lack of sufficient observation. However, the 7 objects which are either AXPs or candidate AXPs (or 10 if we include the 3 Soft Gamma-ray Repeaters in which pulsations have been detected), no binary signature has been found in spite of extensive searches. The strong upper limit on pulse arrival time delay that has been obtained in some of these sources strongly suggests non-binary nature for the AXPs. In addition, the spin change behaviour of the AXPs is also remarkably different from accreting pulsars (Bildsten et al. 1997). In almost all the accreting X-ray pulsars, both spin-up and spin-down episodes have been seen which may be randomly distributed (in persistent sources) or spin-downs in quiescence followed by rapid spin-ups during bright transient phases (in transient pulsars) or long monotonic spin-up and spin-down episodes accompanied by spectral and luminosity changes (e.g. 4U 1626–67, Yi & Vishniac 1999).

The AXPs are in many respect also similar to the X-ray counterparts of the Soft Gamma-ray Repeaters (SGR). The X-ray spectral and timing properties of these two type of objects have strong similarities, half of the AXPs and SGRs are associated with supernova remnants. This has lead to the suggestion that the AXPs are also magnetars in which the X-ray emission is due to magnetic field decay (Thompson & Duncan 1996). The main difference between these two type of objects is the non detection of SGR bursts from the AXPs. However, considering the rarity of the SGR activity among the established SGRs (Kouveliotou et al. 1996), the absence of bursts from AXPs is not a serious issue. From a relatively young age of the AXP, 1E 1841–045 in the supernova remnant Kes 73, Gotthelf, Vasisht, & Dotani (1999) proposed that in the evolutionary track, the AXPs are an early quiescent state of the SGRs. Stability of the X-ray emission properties (spin-down rate, luminosity, spectral shape and pulse shape and fraction) is usually men-

tioned as one important aspect of the AXPs though one has to compare between observations made with different instruments for which the energy band, energy resolution and sensitivity are not identical. To make a rigorous comparison in the stability of the X-ray emission properties we have made new observations of two AXPs with the *ASCA*, four years after two previous observations reported by White et al. (1996) and Corbet & Mihara (1997). The aim was to critically examine the stability of the X-ray emission pattern and more pulse period measurements which may provide support to either the accretion powered or the magnetar hypothesis for these objects.

The source 4U 0142+61 is close to a long period binary pulsar RX J0146.9+6121 and in the *EXOSAT* observations of this field in which pulsations were first discovered, pulsations from both the sources were observed simultaneously (Israel, Mereghetti & Stella 1994). With *EXOSAT*, the 8.7 s pulsations in this source were detected only in the 1.0–4.0 keV range. A binary nature of the system was preferred in spite of a large X-ray to optical flux ratio and absence of pulse arrival time delay. The source was subsequently observed with *ROSAT* and the pulse period was found to be very close to the *EXOSAT* measurement (Hellier 1994). *ASCA* observation in 1994 confirmed the steady spin-down trend and defined the spectral character clearly. A model consisting a 0.4 keV blackbody and a power law with a photon index of 3.7 was found to describe the spectrum well. From a small radius of a few km of the black body emission zone (which probably is on the surface of the neutron star) White et al. (1996) suggested that the black-body component is more likely to be due to a spherical accretion rather than accretion from a disk. A small pulse fraction and energy dependent pulse profile, double peak at low energy and single peak at high energy is characteristic of this pulsar. From *RXTE* observations, the upper limit on the pulse arrival time delay was determined to be 260 ms in the 70 s to 2.5 days range thereby ruling out all types of binary companions except white dwarf or low mass He main sequence star (Wilson et al. 1999). *BeppoSAX* observations during 1997–98 confirmed the spectral characteristics, pulse profiles and spin-down trend (Israel et al. 1999b). Observations spanning 20 years during 1979–1998, with the *Einstein*, *EXOSAT*, *ROSAT*, *ASCA*, *BeppoSAX* and *RXTE* show an overall constant spin-down trend with $\dot{P} = 2.2 \times 10^{-12} \text{ s s}^{-1}$.

Pulsations in the source 1E 1048.1–5937 were dis-

covered from observations with the *Einstein* observatory in 1979 and was confirmed by *EXOSAT* observation in 1985 (Seward, Charles, & Smale 1986). The energy spectrum was found to be a power-law type ($\Gamma = 2.26$) with low energy absorption ($N_H = 1.6 \times 10^{22} \text{ atoms cm}^{-2}$). The relatively harder power-law spectrum and a candidate optical counterpart lead to the speculation that this can be a Be star binary. Several *GINGA* observations established a secular spin-down trend with $\dot{P} = 1.5 \times 10^{-11} \text{ s s}^{-1}$ similar to a few other soft spectrum pulsars (Corbet & Day 1990). Subsequent *ROSAT* observations however revealed an increase in the spin-down rate which is remarkably different from other established AXPs (Mereghetti 1995). The low energy part of the spectrum was first accurately measured with the *ASCA* in 1994 (Corbet & Mihara 1997). However, it could not distinguish between power-law ($\Gamma = 3.34$) and a combination of power-law ($\Gamma = 2.0$) and black-body ($kT = 0.55 \text{ keV}$). During the *ROSAT* and the *ASCA* observations, the spin-down rate remained at a higher level of $3.3 \times 10^{-11} \text{ s s}^{-1}$. A decrease in intensity by a factor of 3 compared to the *EXOSAT* observation was also noticed. *BeppoSAX* observation in 1997 showed that a combined black-body and power-law model fits the data well. The size of the black-body emission zone was found to be of the order of km^2 , identical to other AXPs (Oosterbroek et al. 1998). Compared to other AXPs, the pulse fraction was found to be much larger ($\sim 65\%$) in 1E 1048.1–5937 and has little energy dependence. The power-law component is also relatively harder ($\Gamma = 2 \sim 2.5$) compared to the other AXPs ($\Gamma = 3 \sim 4$). *RXTE* observations in 1996–97 showed yet another change in the spin down rate, now close to that in 1980’s. Long *RXTE* observations established a small upper limit of 60 ms for any pulse arrival time delay for orbital period in the range of 200 s to 1.5 days. Based on this, any binary companion other than low mass helium burning star in a face on system has been ruled out (Mereghetti, Israel, & Stella 1998).

2. Observations and data analysis

Both the sources were observed twice with *ASCA*, in 1994 and in 1998 with about 4 years time difference between the two observations. *ASCA* has two Solid-state Imaging Spectrometers (SIS) and Gas Imaging Spectrometers (GIS) each at the focal plane of four identical mirrors of typical photon collecting area 250 cm^2 at 6 keV. The energy resolution is 120 eV and

600 eV (FWHM) at 6 keV for the SIS and GIS detectors respectively. For more details about *ASCA* please refer to Tanaka, Inoue & Holt (1994). Details of the 1994 observations are given in Corbet & Mihara (1997) and White et al. (1996). In 1998, the GIS observations were made in normal PH mode in which the time resolution is 64 ms and 500 ms at high and medium bit rates respectively. The SIS observations were made with one of the CCD chips, and has time resolution of 4 s. The standard data selection criteria of the *ASCA* guest observer facility, that comprises a cut-off rigidity of charged particles 6 GeV/c, maximum rms deviation from nominal pointing of 0.01 degree, minimum angle from Earth's limb 10° , satellite outside the South Atlantic Anomaly region etc were applied. Data were removed from the hot and flickering pixels of the SIS detectors and also the charged particle events were removed from the GIS detectors based on rise time discrimination. For the two observations of 4U 0142+61, the source photons were extracted from circular regions of radius 6 arc min and 4 arc min around the source for GIS and SIS respectively. In the case of 1E 1048.1–5937, the source photons were extracted from relatively smaller regions of 5 and 3 arc min respectively. For SIS, the background spectra were accumulated from the whole chip excluding a circular region around the source and for GIS it was collected from regions diametrically opposite to the source location in the field of view.

2.1. Period analysis

To calculate the pulse periods accurately, barycentric correction was applied to the arrival time of each photon and light curves were extracted from the pair of GIS detectors with a time resolution of 0.5 s in the energy band of 0.5–10.0 keV. Epoch folding method was applied to obtain the pulse periods approximately and templates for the pulse profiles were created by folding the light curves at the approximate pulse periods. Subsequently, the light curves were divided into eight segments of equal length and pulse profiles were created from each of these segments by applying the same epoch and pulsation period. The relative phases of the pulses were then evaluated by cross correlating the pulse profiles with the respective templates. A linear fit to the relative phases with their pulse numbers gave the correction necessary to obtain the accurate pulse period. The 1998 observations of the two AXPs resulted in new measurement of pulse periods at these epochs and from the 1994 observations we obtained

Fig. 1.— The background subtracted pulse profiles of 4U 0142+61 obtained with the GIS in three energy bands are plotted for two cycles. A change in the pulse profile, from double peaked at low energies to single peaked at high energies can be noticed.

similar pulse periods as reported earlier, with reduced uncertainty for 4U 0142+61. The pulse periods obtained for the two sources are given in Table 1. The pulse profiles of the two sources in three energy bands are shown in Figure 1 and Figure 2. The pulse fraction, defined as the ratio of the pulsed to total flux, was calculated from background subtracted pulse profiles in the 0.5–10.0 keV band. Pulse fractions were found to be identical in both the observations, $\sim 9\%$ and $\sim 75\%$ in 4U 0142+61 and 1E 1048.1–5937 respectively. In 4U 0142+61, the pulse profile shows energy dependence, from double peaked in low (0.5–1.5 keV) and medium (1.5–4.0 keV) energy to single peaked in high (4.0–8.0 keV) energy, associated with increase in the pulse fraction. In 1E 1048.1–5937, on the other hand, the pulse profile and pulse fraction are almost identical over the *ASCA* energy range. Light curves of the two sources did not show any intensity variations at minutes to days time scale.

2.2. Spectral analysis

In 4U 0142+61, a simple absorbed power-law fit shows large residuals at low energy and addition of a black-body component results in acceptable fit. For the 1998 observation, inclusion of the black-body component improved the reduced χ^2 from 2.88 to 0.94 and 1.23 to 0.76 for the GIS and SIS respectively. Similar improvement in fitting was reported by White et al. (1996) for the 1994 observation. The

Fig. 2.— The background subtracted pulse profiles of 1E 1048.1–5937, similar to Figure 1. The pulse fraction of this source is $\sim 75\%$, highest among the AXPs.

photon index of the power-law component obtained from the SIS data for the two observations are identical, $\Gamma = 3.3$. The photon index from the GIS data is slightly different from the SIS value, $\Gamma = 3.9$, but it is identical for the two observations. The temperature of the black body component obtained from both SIS and GIS are identical, 0.39 keV, in both the observations and the flux in the two components are also identical. The difference in the photon index between the SIS and GIS can possibly be attributed to calibration uncertainty, because the in-flight spectral calibration of the spectrometers are done with sources which have relatively harder spectra. The SIS and GIS spectra of the 1998 observation are shown in Figure 3 along with the best fitted models for the respective detectors and the residuals to the model spectra.

For the other source 1E 1048.1–5937, Corbet and Mihara (1997) showed that the power-law and black-body with power-law models could not be distinguished from spectral analysis of the *ASCA* data. We have found different and deeper minima in the χ^2 for the black-body with power-law model. The improvement in χ^2 , ($\Delta\chi^2$ of 41 for 292 degrees of freedom and 28 for 261 degrees of freedom for the 1998 and 1994 observations respectively, both indicating probability of chance occurrence less than 10^{-3}) therefore favours the inclusion of a black-body component. The black-body component has also been detected with *BeppoSAX* (Oosterbroek et al. 1998). The best fitted power-law plus black-body model gives a photon in-

Fig. 3.— The observed SIS and GIS energy spectra of 4U 0142+61 shown with histograms for the model spectra folded through the responses matrices and the residuals.

dex of ~ 3.0 , black body temperature of ~ 0.56 keV and column density of $\sim 1 \times 10^{22}$ atoms cm^{-2} . The spectral parameters are identical in both the *ASCA* observations and are given in Table 2. Due to relative weakness of this source, simultaneous spectral fitting was carried out with the GIS and SIS data for the 1998 observation (Figure 4). However, for the 1994 observation, the SIS were operated in FAST mode and spectra were available only from the two GIS detectors.

3. Discussion

3.1. Period changes and Emission stability

The pulse period measurements of 4U 0142+61 is rather scarce except for the last two years (Figure 5). In spite of the source being very bright, with a flux of more than 10^{-10} erg cm^{-2} in the 2.0–10.0 keV band, a pulse fraction of only about 10% has restricted the individual pulse period measurements accurate to only about $\Delta P/P \sim 10^{-5}$. A linear fit to the pulse period history shows that of the 10 measurements available, only during the 1994 *ASCA* observation the pulse period measurement was slightly different (2.5σ) from the linear trend. If the reported errors of all the measurements are taken at their face value, the linear fit gives a reduced χ^2 of 1.7 for 8 degrees of freedom. It therefore can be concluded that the recent *ASCA* measurement together with the previous results is consistent with a constant spin-down

Fig. 4.— The SIS and GIS energy spectra of 1E 1048.1–5937 along with the residuals. The histograms represent the best fitted model folded with the response matrices. A simultaneous fitting of the SIS and GIS spectra was performed.

rate. The observations are not yet sufficient to clearly identify any significant variation from a constant spin-down rate.

In the source 1E 1048.1–5937, departure from a linear spin-down is already known (Mereghetti 1995; Oosterbroek et al. 1998). In this source, an order of magnitude larger spin-down rate and better pulse period measurements ($\Delta P/P \sim 10^{-6}$), owing to a high pulse fraction ($\sim 75\%$), help us to identify three different epochs of spin-down history. Though the method adopted for calculating the errors in the pulse period is not known for all the observations and the uncertainty level is likely to be nonuniform, a constant spin-down trend can be ruled out without any doubt. A linear fit to the pulse period history with the reported errors gives a reduced χ^2 of 4500 for 11 degrees of freedom. Including the 1998 *ASCA* observation (see Figure 6) with the recent *BeppoSAX* and *RXTE* observations, we find that from 1996 the source has a spin-down rate of $(1.67 \pm 0.02) \times 10^{-11} \text{ s s}^{-1}$. This is a factor of 2 smaller than the spin-down rate of $(3.29 \pm 0.03) \times 10^{-11} \text{ s s}^{-1}$ during the 1994–1996 period. The present spin-down rate is closer to the value of $(1.5 \pm 0.5) \times 10^{-11} \text{ s s}^{-1}$, measured during the *Einstein*, *EXOSAT* and *GINGA* observations made in the period 1979–1988. The spin-down rate is much closer to being constant during these three epochs with reduced χ^2 of 0.8, 7.7, and 36 for 3, 3, and 1 degrees of freedom respectively.

These two sources do not show flux variability on time scales from a few minutes to days. In the *ASCA* observations of both the sources separated by 4 years we have found that the overall intensity and spectral parameters have remarkable stability. A difference between the GIS and SIS photon index that has been found in 4U 0142+61, is due to calibration uncertainties. The spectral parameters obtained from the 1998 GIS and SIS observations are identical to the 1994 values. The spectral parameters obtained from the simultaneous fitting of the GIS and SIS spectra are similar to the *BeppoSAX* values obtained during 1997–1998. In 4U 0142+61, the flux history shows a rms variation of 15% around the average value (Figure 5), and multiple measurements with the same instrument (*ASCA* and *BeppoSAX*) gave almost identical flux. In 1E 1048.1–5937, the over all intensity during the two *ASCA* observations and one *BeppoSAX* observation in between are within 10% of the average value. The 2.0–10.0 keV fluxes during the *Einstein* and *ROSAT* observations are estimated by extrapolating the measurements in the low energy bands of 0.2–4.0 keV and 0.5–2.5 keV respectively, and using a rather low photon index of 2.26, obtained by *EXOSAT*. The flux during the *GINGA* observation is estimated by comparing the pulsed fluxes during the *GINGA* and *EXOSAT* observations and assuming that the pulse fraction remained same. The flux measurements from the previous observations as shown in the bottom panel of Figure 6 are about a factor 3 higher than the recent measurements with *ASCA* and *BeppoSAX*. We note that there is some overestimation in extrapolation of the soft X-ray measurements with *Einstein* and *ROSAT* due to a smaller photon index used, and the flux estimates from *EXOSAT* and *GINGA* could be overestimated due to contribution from the nearby bright and variable source η -Carina, which is only 0.4° away and is about 15 times brighter than 1E 1048.1–5937 (Corcoran et al. 1998; Ishibashi et al. 1999). In view of the stability of the flux during 1994–1998, as obtained from the imaging instruments *ASCA* and *BeppoSAX*, it is possible that the overall intensity of this source does not vary at a few years times scale. The spectral parameters from the two *ASCA* observations are also identical and consistent with the values obtained with *BeppoSAX* in between. However, we note that in 1E 1048.1–5937, the absorption column density obtained from the two *ASCA* observations are identical and a factor of 1.5–2 larger than the *BeppoSAX* measurement in between. This

Fig. 5.— The pulse period and flux history of 4U 0142+61. The straight line shows the best fit for a constant spin-down. The pulse period measurements with *ASCA* are marked with filled circles and the open circles are for all the other observations mentioned in the text.

difference is somewhat larger than the known calibration difference between the two instruments (Orr et al. 1998).

Some Low Mass X-ray Binaries (LMXB) have also been detected at low luminosity levels ($\sim 10^{33}$ erg s $^{-1}$; e.g. Cen X-4, Aql X-1, see Tanaka & Shibazaki 1996 and references therein), understood to be quiescent phase of the Soft X-ray Transients (SXT). Usually the LMXB sources show both short and long term irregular intensity variations and many also show quasi-periodic oscillations, bursts, dips or orbital modulation. Even though the AXP's do not show significant temporal variations other than the pulsations, which is somewhat different from typical characteristics of low-luminosity LMXBs, this itself is not a strong argument against the AXP's being LMXBs. One LMXB which has some properties similar to the AXP's is 4U 1626-67. The X-ray luminosity, magnitude of spin-change rate, pulse period, and flux stability over very short to years time scale of this source are similar to the AXP's. But, presence of both spin-up and spin-down, quasi-periodic oscillations, optically bright accretion disk, and a hard X-ray spectrum makes it different from the AXP's.

Fig. 6.— The pulse period and flux history of 1E 1048.1-5937. The lines are used to identify the different spin-down epochs. The pulse period measurements with *ASCA* are marked with filled circles and other observations with open circles.

3.2. Accretion torque in the common envelope evolution model

It has been proposed that the AXP's are recent remnants of common-envelope evolution of high-mass X-ray binaries (van Paradijs et al. 1995; Ghosh et al. 1997). In this model, the pulsar is rotating near its equilibrium period, close to the Keplerian period at the innermost part of the disk. If the pulsar is rotating at the equilibrium period, small changes in the mass accretion rate cause alternate spin-up and spin-down episodes. The over all spin-down is explained with the assumption that in the absence of a companion star as the source of mass accretion, the mass accretion rate from the disk decreases slowly on viscous time scale. The equilibrium period of the pulsar is inversely related to the mass accretion rate and shows secular increase. For 1E 1048.1-5937, which has a pulse period of 6.5 s and luminosity of 6.3×10^{33} erg s $^{-1}$ for a distance of 3 kpc (or in a more favourable case, 7×10^{34} erg s $^{-1}$ if the source is at a distance of 10 kpc), the magnetic field strength inferred for an equilibrium rotator (Frank, King & Raine 1992) is $B = 10^{11} (P/3)^{7/6} L_{35}^{1/2} = 6.2 \times 10^{10}$ (or 2.1×10^{11}) gauss. Here, and in what follows we have assumed a neutron star with mass $M = 1.4 M_{\odot}$, radius $R = 10^6$ cm, and moment of inertia $I = 10^{45}$ gm cm 2 . A pulse period of P implies that if in equilibrium, the co-rotation radius or in this case the radius of the inner disk is $r_M = (GM)^{1/3} (P/2\pi)^{2/3}$. The infalling

Fig. 7.— The X-ray luminosity and pulse fraction of the AXPs and SGRs are plotted against the magnetic field strength assuming that these objects are magnetars. Two values of the luminosity are plotted for 1E 1048.1–5937 to show the uncertainty in its distance and same has been done for SGR 1900+14 to show the variability in its X-ray emission. Distance of 1RXS J170849.0–400910 is taken to be 10 kpc and that for other sources are the best available estimates.

material from the disk carries a positive angular momentum of $\dot{M} (GM_{\text{rM}})^{1/2}$. The torque can also be expressed in terms of the pulse period P and the X-ray luminosity L_X as $RL_X (P/2\pi GM)^{1/3}$. Even if we assume that all of the X-ray emission is a result of disk accretion, the accretion torque is only 1.1×10^{31} (or 1.2×10^{32}) $\text{gm cm}^2 \text{s}^{-2}$. To achieve the observed spin-down rate for a neutron star with moment of inertia 10^{45} gm cm^2 , the negative torque required to be imparted onto the neutron star is $I\dot{\Omega} = 4.9 \times 10^{33} \text{ gm cm}^2 \text{s}^{-2}$. This is a factor of 450 (or 40) larger than the accretion torque, and in the common envelope evolution model, a negative dimensionless torque of this magnitude is required to spin-down the pulsar at the observed rate. In other words, the spin-down rate of this source is much larger than what can be achieved with disk accretion onto a neutron star with a luminosity of less than $10^{35} \text{ erg s}^{-1}$. 1E 1048.1–5937 does not fit in the classical picture of $\dot{P}$ vs $PL^{3/7}$ of the equilibrium rotators (Ghosh & Lamb 1979). In addition, the two *ASCA* observations made during the two epochs which have a factor of 2 different spin-down rates, do not show significant difference in the

luminosity or the spectral parameters.

Among the other AXPs, 1RXS J170849.0–400910 (Sugizaki et al. 1997; Israel et al. 1999a) and 1E 1841–045 (Kes 73, Vasisht & Gotthelf 1997; Gotthelf et al. 1999) have relatively large spin-down rate of 2.2×10^{-11} and $4.1 \times 10^{-11} \text{ s s}^{-1}$ respective, while the X-ray luminosity is in the range of $10^{35} - 10^{36} \text{ erg s}^{-1}$. In the common envelope evolution model of the AXPs, a faster spin-down compared to the torque provided by the accreting matter can be a potential problem for these two sources also. For this model to be correct for the AXPs, a very fine tuning of the mass accretion rate is required. All the sources need to have disk accretion rate a tiny fraction larger than the propeller regime. Li (1999) have identified several other problems in the context of applicability of this model to the AXPs. Most notable is the limited lifetime of an accretion disk around a solitary neutron star compared to the response time scale of the neutron star to changes in the accretion torque. One possible alternative is that the spin-down is due to magnetically driven wind from an accretion disk, proposed also for SGR 1900+14 (Marsden, Rothschild, & Lingenfelter 1999), but this will require a harder X-ray spectrum than what has been observed. Chatterjee, Hernquist & Narayan (1999) proposed a scenario in which the AXPs are formed as single neutron stars with fossil disks made from fallback material from the supernovae explosions. In this model, the spin-down from an initial period of a few ms to $\sim 6 \text{ s}$ is due to strong propeller effect at some period when the accretion rate is very low. But, if accretion is the correct phenomenon in the AXPs, as high spin-down goes on in presence of substantial accretion, spin-down due to wind outflow seems to be more plausible than accretion induced angular momentum loss. However, it should be remembered that the classical equilibrium disk picture assumed here is often found not to be the most appropriate description for the X-ray pulsars (Bildsten et al. 1997).

3.3. Magnetar model

In view of a very narrow mass and type allowed for any binary companion, and several arguments against the common envelope evolution model, the magnetar model seems to be the most likely one for the AXPs. If the spin-down is due to magnetic braking, dipole field strength of the order of 10^{14} gauss is estimated for these sources. A nearly constant spin-down property was thought to favour the magnetar model

over a binary scenario. In two AXPs, 1E 1841–045 (Gotthelf et al. 1999), and 1RXS J170849.0–400910 (Kaspi, Chakrabarty & Steinberger 1999), there is very strong evidence for constant spin-down, whereas in 1E 1048.1–5937, deviation from a linear trend is clear. Recently, a deviation has also been detected from SGR 1900+14 (Woods et al. 1999). 1E 2259+586, the most frequently observed AXP, has provided an interesting pulse period history. Observations made for about 15 years with many instruments preceding *RXTE* showed considerable variation in the spin-down rate (Baykal & Swank 1996). But, the pulse-coherent timing observations with *RXTE* proved it to be otherwise, at least for a period of last 2.6 yr (Kaspi et al. 1999).

Two scenarios have been proposed which can explain the changing spin-down rate even when the overall braking is due to the ultrastrong magnetic field. Melatos (1999) showed that for reasonable neutron star parameters, a radiative precession effect may take place which can give the observed spin-down variations with time scale of about 10 years. It will be possible to verify this scenario when more pulse period measurements become available in the next few years. Woods et al. (1999) have identified a possible *braking glitch* in SGR 1900+14 close to the time when SGR activity was very strong. But if the spin-down variation is related to the SGR activity, similar activities should have been observed from 1E 1048.1–5937 and 1E 2259+586. We have found that all the gamma ray bursts observed with the BATSE for which the estimated positions are within 2σ of these AXPs (about 30 GRBs around each AXP), have strong high energy emission unlike the SGR bursts. Heyl & Hernquist (1999) have proposed that the spin-down variations can be explained as glitches (similar to radio pulsars) superposed on constant spin-down. But, with recent pulse period measurements of 1E 1048.1–5937 and SGR 1900+14, this will require too many glitches, one before almost every observation unless there are *braking glitches*, never observed in radio pulsars.

In the magnetar model, the X-ray emission is due to decay of the magnetic field. The energy generated at the core is transported to the crust along the magnetic field direction. The black body component of the spectrum is thermal emission from the hot spots at the magnetic polar regions and the power-law component is part of the thermal emission reprocessed by the magnetic field and the environment. Investigation is required about the expected pulse

profile and its energy dependence. Time and/or energy dependence of the pulse profile as has been observed in SGR 1806–20 (Kouveliotou et al. 1998) and SGR 1900+14 (Hurley et al. 1999; Kouveliotou et al. 1999; Murakami et al. 1999) also requires to be addressed. A double peaked pulse profile at low energy and single peaked profile at high energy are observed in 4U 0142+61 (Figure 1). The pulsation is very weak in some sources (only 5–10% in SGR 1806–20 and 4U 0142+61), and 75% in 1E 1048.1–5937. If the pulsation is due to confinement of the heat in the magnetic polar regions by the magnetic field, a correlation between magnetic field strength and pulse fraction should be observed. But, it is likely to be smeared by the geometric effect of individual sources, i.e. the orientation of the spin and magnetic axes with respect to the line of sight. In the magnetar model, there are two mechanisms by which X-rays can be generated. If the X-ray emission is powered by decaying magnetic field, the luminosity is a very strong function of the magnetic field strength, $L_x \propto B^4$ (Thompson & Duncan 1996). Alternate process of X-ray generation is particle acceleration by Alfvén waves resulting from small scale fracture of the crust, in this case $L_x \propto B^2$. The X-ray luminosity and pulse fraction of five confirmed AXPs and two SGR sources are shown in Figure 7. against the magnetic field strength. The later is estimated from pulse period and the overall spin-down rate assuming $B = 3.2 \times 10^{19} \text{ (P}\dot{\text{P}})^{1/2} \text{ gauss}$. Though there is uncertainty in the luminosity of some sources (see the caption of Figure 7), a 2nd or 4th power correlation between L_x and B does not seem to be present. There is also no correlation between pulse fraction and the magnetic field.

A clustering of the pulse period of 10 sources (7 AXPs and 3 SGRs) in the 5–12 s range also needs to be addressed, when the magnetars are expected to be alive in X-ray until they have slowed down to a pulse period of about 70 s (Duncan & Thompson). The magnetars are expected to be radio quiet due to suppression of pair creation at high magnetic field (Baring & Harding 1998), and this seems to be true for most sources.

Changes in luminosity or small changes in the spectral parameters can be a result of varying activities in the core, the heat generated from which is transported to the surface along the direction of the magnetic field at time scale of a few years. Variability study of AXPs with very high sensitivity may rule out magnetar model if significant change in column

density is observed. This will indicate the presence of accretion disk and wind in the neighbouring area. The *BeppoSAX* and *ASCA* observations give identical column density for 4U 0142+61 but slightly different column density in case of 1E 1048.1–5937. However, multiple observation of the later source with the same instrument is found to give identical value indicating that the difference between the two instruments can also be a systematic effect.

4. Conclusion

Using multiple observations of two AXPs with the *ASCA* we have found remarkable stability in the intensity, spectral shape and pulse profile over a 4 years period. For the source 1E 1048.1–5937, we have confirmed that similar to other AXPs, the spectrum consists of a power-law component and a black body component. The spin-down trend of 4U 0142+61 is consistent with a constant rate whereas in 1E 1048.1–5937 we have clearly identified three different spin-down epochs. We have shown that the fast spin-down of some of the AXPs is difficult to achieve with disk accretion. Hence the common envelope evolution scenario of AXPs is unlikely to be the case, unless the spin-down is due to wind outflow from the disk. In this case also, the stability of X-ray emission in spite of varying spin-down rate remains unexplained. The significantly different spin-down rates of 1E 1048.1–5937 in different epochs are also difficult to reconcile in the magnetar model, unless precession is at work. But the flux stability and lack of variation of the spectral parameters appear to favour the magnetar model.

We thank an anonymous referee for many suggestions which helped to improve a previous version of the manuscript. B. Paul was supported by the Japan Society for the Promotion of Science through a fellowship.
